The Importance of Integrated Software Solutions in Troubleshooting Gear Whine

Paul Langlois

NVH — noise, vibration and harshness — is a key issue in the design and development of modern transmission and drive-line systems. A combination of regulations and consumer expectations drive a demand for reduced noise in all drivetrain components. Further demand is driven by the growing trend towards EV and HEVs where noise from inter- nal combustion engines is intermittent or no longer present and the contribu- tion of transmission noise to overall vehicle noise becomes dominant, mak- ing it more difficult to achieve customer satisfaction. So how do these problems occur? How can they be controlled? And what role can integrated software play in the troubleshooting process in order to obtain efficient and effective solutions?

Gear Whine Analysis Requires a System Level Approach

Gear whine is an NVH phenomenon most commonly sourced from transmis- sion error (TE) at engaged gear mesh- es. Theoretically, an infinitely stiff gear set with perfect involute form and no misalignment would transfer angular velocity exactly in accordance with the designed ratio. However, in reality, no gear is perfect and, for example, tooth bending and misalignments caused by deflections of the system contribute to real gears not performing to this ideal. TE is the difference between the angu- lar position that the output shaft of a drive would occupy if the drive were perfect and the actual position of the output (Ref. 1). Other potential, but less common, sources of gear whine whose fundamental frequency is also at once- per-tooth include axial shuttling forc- es — where the axial location of the resultant force varies through the mesh cycle, resulting in a varying moment on the gears; and friction forces from the relative sliding at the gear mesh (Ref. 2).

Transmission error can be considered a periodic relative displacement at the gear mesh in the line of action caused by less-than-ideal meshing conditions. The TE can dynamically excite the trans- mission through a path from the gear mesh, through the shafts and bearings and into the transmission housing. Gear whine is the name given to the resulting tonal noise radiated from the housing or transmitted from the housing to be radiated elsewhere. Gear whine should therefore not just be considered a *gear* problem; it is a *system* problem with the gears as the exciters of the system.

As a typical source-path-respond- er dynamic phenomenon, gear whine issues can be difficult to troubleshoot. It is often considered that the solution to gear whine can always be found by optimizing the gear microgeometry to minimize the excitation. Although con- trolling transmission error will reduce gear whine, and can often be the best approach to doing so, a gear mesh with minimal transmission error may still be a cause of gear whine issues if the rest of the system is highly sensitive to excita- tions at the gear mesh. Each stage of the process should, and may have to, be con- sidered in the search for a potential solu- tion. Further, by increasing the solution space to include the optimization of gear macro geometry for gear whine and via consideration of the stiffness and mass of the supporting structure and housing, greater improvements can be achieved.

As gear whine is a system-level NVH issue, for simulation of these contribu- tions and virtual testing of potential solutions a full system level modelling and analysis approach is required.

A Full Testing and Simulation Methodology

To solve NVH problems, a combina- tion of experience and the right tools are required to find solutions with minimal cost and timescale. An efficient NVH troubleshooting methodology requires a process where accurate measurements and detailed CAE simulations can be performed side by side and data pro- cessed and communicated error-free between testing and analysis teams using integrated software solutions. Integrated software solutions for gear whine NVH are those that can perform measured data capture and analysis and all rel- evant system-level simulations in one integrated environment with seamless data transfer — such as those, for exam- ple, offered by SMT (Fig. 1). The pur- pose of this article is to discuss the role these integrated software solutions play in this process, with the understanding that it is beyond the scope of this article to describe the complete problem-solv- ing methodology.

The first recommended step would be to check manufacturing and assembly

Figure 1   An integrated software solution for gear whine combining measured data capture and analysis with system-level simulations in a single environment with seamless data transfer.

quality. If quality is poor, e.g. — outside the required tolerances — then TE can be high and these issues need to be resolved before steps in addressing the design are taken. Software can play an important role even at this stage, where cylindrical gear manufacturing simulation achieved by SMT *MASTA* software (Ref. 3) can help improve manufacturing quality and resulting TE. In addition, the same soft- ware can be used to carry out parametric studies to identify and adjust manufac- turing tolerances to reduce assembly-to- assembly-related TE variation.

Software plays two main vital roles in the further troubleshooting process: 1) within the test environment, where high- fidelity data logging is required to cap- ture test results and where results need to be processed using data analysis tools to effectively analyze the measurements and identify the features of interest and the main contributors from the system to those features; and 2) within the sim- ulation environment where state-of-the- art, system-level simulation tools are required to perform a number of simu- lations of aspects of the system — details of which will be described later in this

Figure 2   A system-level transmission simulation model.

article. Correlation between simulation and test can be made, and the simulation model then used as a virtual environ- ment for assessing the effect of potential solutions on all requirements and tar- gets. Changing component parameters in a virtual environment is a quick, low- cost approach that minimizes the need for expensive and time-consuming hard- ware trial-and-error loops.

Integrated software solutions allow all these tasks to be performed in a sin- gle software environment. At the test- ing stage, data from proprietary, porta- ble hardware for both noise, vibration and transmission error measurement can be captured, post-processed, and ana- lyzed, using in this case SMT's TE and NVH data capture and analysis soft- ware — *MEASA*. Further, the measured data analysis tools can be linked to SMT's
Figure 3 Measured noise displayed as a waterfall plot with excitation orders automatically labelled via data from a system simulation model.

mentioned transmission design and analysis software, *MASTA* (Ref. 3), where orders from potential excitations within a corresponding analysis model of the sys- tem can be passed to easily identify contributions from transmission components while processing measured data.

Within a simulation environment, *MASTA* allows for analysis of many aspects of the problem; a single model of the system is easily built within the software (Fig. 2). This single set of param- eterized inputs can then be used to per- form a number of analyses for a num- ber of failure modes and phenomena of interest, using auto- matically construct- ed analysis mod- els of differing levels of fidelity. Analyses of interest for gear whine include: stat- ic analyses of the full system under a num- ber of operating loads to calculate deflections of the system and their effect on durability of components; quasi-static analyses of the loaded gear mesh contact conditions to calculate contact stresses, root stresses, transmis- sion error and shuttling forces; modal analyses of the full system to calculate system-natural frequencies, mode shapes and modal energy content; and gear whine analyses of the full system to cal- culate the dynamic response of the sys- tem to excitation by transmission errors.

Test Data Capture and Data Analysis Software

For gear whine issues typical measure- ments considered include noise mea- surements via microphones, casing vibration measurements via accelerom- eters, and transmission error measure- ments via angular encoders.

Measurements of gear whine should include tests performed in-vehicle that capture the full operating range through, for example, vehicle accelerations at dif- ferent throttle levels and vehicle coast- down. Further dyno rig tests should be performed to isolate and understand transmission and driveline noise sources. Care must be taken in correlating any rig test results with those of vehicle tests and the original subjective noise prob- lem. Different boundary conditions on the rig, as compared to in-vehicle, can significantly change the dynamics of the system and subsequent frequency content of problem areas (Ref. 4).

Accurate data acquisition requires calibrated microphones and acceler-

ometers and high-fidelity data logging. Further, an accurate speed signal is required for analysis of component orders. Measurement data can be captured and analyzed using *MEASA* data capture and analysis software. Data analysis tools allow the user to process the data in a number of ways. By linking to a model of the transmission system under consideration, potential excitation orders and the components and harmonics to which they correspond may be imported into the data analysis tools to allow easy identification of the main contributions to specific orders and to the total noise/ vibration content. Critical plots given include waterfall plots and order cuts giving quantitative results for the noise due to specific sources and their promi- nence with respect to total noise (Fig. 3). Although less common than noise and vibration measurements, the source of gear whine — loaded transmission

error — can also be measured using angular encoders. For a transmission or driveline system on a test rig, encod- ers may be placed on the input and out- put shafts in order to measure the whole gearbox, or may be placed straddling a sub-system to measure just that sub- system. As with noise and vibration test results, TE test results may be captured and analyzed using *MEASA*. Fourier analysis can be performed to identify the contributions from different stages and angular TE values can be converted to linear via the base radius values for the gears. A link to a model of the system allows import of gear mesh orders and their harmonics for easy identification within the data analysis tool.

Using these measurement and data analysis techniques, the nature of the noise issue can be quantified and the contributions from the potential excitations in the transmission identified. But how can design changes be made, their effect on the problem assessed, and solutions found efficiently and cost-effectively? This is the role of advanced trans- mission and driveline simulation software within the troubleshooting methodology.

Full System Simulation

Once a gear whine issue has been identified and the contributions clarified via measurement and data analysis techniques, simulation software plays a vital role in efficiently assessing potential solutions. As gear whine is a system-level issue, where solutions may be considered from gear macro geometry design, gear microgeometry design, system stiffness and mass properties and the transmissi- bility of TE to the casing, state of the art system-level software is required to be able to perform various analyses of inter- est. Design changes need to be assessed effectively — not just for their effect on the noise problem at hand — but also for other considerations of importance in the design process so as, for example, not to compromise durability.

Such durability, loaded tooth contact and dynamic response analyses may be performed using standalone commercial FE packages. However, this approach is problematic as it requires models with different levels of fidelity to calculate each aspect. What's more, models are very difficult to set up and do not lend themselves well to analyzing the effects of design changes easily and quickly. On the other hand, integrated CAE soft- ware such as *MASTA* provides tools for engineers to perform these analy- ses using a single model and parameter set. And, model generation is rapid and provides the flexibility to make complex design changes on the fly, seeing imme- diate results within a seamless work- flow. Analyses are fast enough to enable parameter space DOE studies, including assessing the robustness of any design changes to the expected variability in actual parts due to manufacturing and assembly tolerances.

A range of analyses relevant for gear whine problems can be performed on the system-level model. To begin, a number of static analyses are usually performed covering the operating range to calculate deflections of the system, including misalignments at gear meshes, and durability results for components. Baseline durability results should be obtained and compared with results when design changes are made
Figure 4   Hybrid FE and Hertzian-based loaded tooth contact analysis.

Figure 5 Measured and simulated loaded contact patterns.

to check that no compromise in durability is introduced. The system deflec- tion model consists of an FE-based model where shafts are considered as Timoshenko beam elements; bearings are represented via a bespoke non-linear contact formalism, taking into account the full geometry details; clearances, pre-loads, etc., gear meshes are represented as bespoke non-linear contact models; and housings and complex asymmetric shafts are included via stiffness and mass matrices obtained via dynamic reduction from a full FE model of the geometry. Durability results for bearings, gears, shafts and other coupling components are obtained by passing deflections and loads from the analysis results to imple-mentations of the relevant international standards (Refs. 5–7).

Although it should be noted that the solution to gear whine does not always lie in optimizing gear microgeometry, this is often the first area of investiga-tion due to its relative ease. Further, if late in the development process, this is often the easiest option to implement due to the minimal change to manufac- turing processes and tooling required. Calculation of TE can be performed using a loaded tooth contact analysis (LTCA). Torque, misalignment, gear macro and microgeometry are used as inputs. It is very important to use an accurate LTCA in order to get an accu- rate calculation of TE. A hybrid FE and Hertzian, contact-based formalism are used to accurately capture the stiffness at each contact location while providing a fast calculation suitable for assessing microgeometry parameter changes and robustness to tolerances (Fig. 4). Such a calculation is comparable in accuracy to a full FE contact analysis while being many orders of magnitude faster. An FE

model of the gear macro geometry is built automatically in the software and used to obtain the overall bending and base rotation stiffness of the gear teeth, with consideration made for coupling between teeth. This bending stiffness is combined with a Hertzian line con- tact formalism to calculate the overall stiffness of any potential contact points. Potential contact lines are split into strips and force balance and compatibil- ity conditions are formulated and solved (Ref. 8) to calculate the load distribution across the mesh and the transmission error for the input torque. This LTCA can be used to optimize gear microge- ometry and macro geometry for mini- mal transmission error. Consideration must be given to the entire operating range of loads and the robustness of the proposed design to variation in load and misalignments, as well as variation in gear microgeometry within the manu- facturable tolerance range.

It is often assumed in the analy-sis workflow described above that the deflections of the system affect the tooth contact — but the tooth contact con- ditions do not affect the deflections of the system. Hence, as above, a calcula- tion of misalignments is first performed using a static system-level model, and these misalignments, assumed constant throughout the mesh cycle, are used as inputs into the tooth contact calcula- tion. This assumption is often — but not always — valid. In a number of impor- tant cases, such as the tooth contact conditions of a planet gear, the inter-action between the two meshes of the planet means that the system deflection and tooth contact conditions need to be solved in a coupled calculation. In such a calculation the assumption of a fixed misalignment throughout the mesh

cycle is removed and the variation in misalignment is calculated. Further, for planetary systems where contact con- ditions may vary, as the planet carri- er rotates, such a coupled calculation is required. The software solutions dis- cussed here also provide such a calcula- tion.

Tooth contact analysis results can often provide good validation that the analysis model is set up and perform- ing correctly. A contact patch test is a relatively easy and common test to per-form and contact patch test results can be compared directly against analysis results (Fig. 5). If correlation is good, this gives confidence in the analysis model, implying that calculated mis- alignments, microgeometry inputs, and calculated load distribution under the tested loads are accurate. Further, if TE measurements have been performed, measured and calculated, TE can be directly compared.

Analysis of the dynamics of the system can be performed via modal and har-monic response analyses. For a modal analysis of the system at a given input load, a linearized model of the non-lin-ear static analysis model at that load is automatically built. The natural frequen-cies and corresponding mode shapes can therefore be calculated for differ- ent operating loads. Campbell diagrams can be used to identify potential excita- tions of the system where, for example, gear mesh frequencies or their harmon- ics cross the natural frequencies of the system. Further, the energy content of the mode shapes can be visualized and investigated to identify the main con-tributing components to those poten- tial resonances (Fig. 6). A target would be to minimize the number of natural frequencies within the operating range

while also separating any way in which do lie within the range from each other.

The method of calculation of the system response to the transmission error introduced by Steyer et al (Ref.9) can be used to calculate the casing acceleration at virtual accelerometer locations. As the excitation is periodic and the stiffness around the loaded condition can be considered linear, the calculation can be performed very quickly in the frequency domain. Static transmission error is the assumed excitation input of the system and the first step is to calculate the dynamic force at the gear meshes, which leads to a relative displacement at the mesh given by this transmission error. This force is known as the dynamic mesh force that is calculated from the dynamic compliances at each side of the gear meshes. The dynamic mesh force is then applied as an excitation to the system model to calculate the response at any point on the system to this excitation. Waterfall charts can be plotted of dynamic response for any point on the model (Fig. 7) and compared with accelerometer and/or microphone data obtained via noise and vibration tests.

Once a virtual model is correlated with test data, contributing modes to problem frequencies can be identified via the waterfall charts and natural frequencies. Then, the contributing components to those modes can be identified with mode shapes and energy contributions. With the results obtained, the design of these components can be adjusted to improve the dynamic response of the analysis model. Once the desired results are obtained, the design changes can be implemented on a prototype and tested again to confirm the expected improvements.

Benefits of an Integrated Software Approach to Troubleshooting Gear Whine
• Reduced product development time by targeting solutions in a virtual testing environment.
• Reduced product development cost by minimizing component testing.
• Allows production variation to be investigated and minimized prior to product launch.

Summary

The development cycle of transmission systems is a complex and costly process. With increased demands for lower-noise transmissions and drivelines driven by markets such as EV and HEVs, more pressure is being placed on designers to design for low noise and for analysts to solve known gear whine issues quickly and efficiently. Quick solutions with minimal cost can be found with a combination of solid methodology, experience and the right software tools. Software plays a vital role within this process. Assessing, controlling and fine-tuning designs for gear whine within an integrated CAE environment, such as that offered by SMT, where test data capture and data analysis, together with advanced simulation methods, are seamlessly integrated, provides engineers with the flexibility and freedom to achieve new levels of quality otherwise too costly and time-consuming to achieve through physical prototyping alone.
